A Total Returns Index for Investor Housing in New Zealand

Bob Hargreaves and Song Shi

Finance, Banking and Property Department

Massey University, Palmerston North

New Zealand

Keywords: Total returns index, investor housing, New Zealand.

Abstract:

A total returns index for investor housing was developed by utilising the Quotable Value New Zealand house price index and the Department of Building and Housing rental series. Survey information was then used to establish the relationship between gross rents and net income. The index was tested for sensitivity and correlation analysis used to compare the returns between cities. Analysis of the data showed that over the last decade rental yields have continued to decline but total returns have increased due to the appreciation in house prices. Regional total returns showed variability with higher yields from slower growing areas being insufficient to offset lower yields from faster growing areas. Negative correlations in the total returns between some cities were identified, suggesting there are opportunities for investors to maintain returns and reduce risk by diversifying their property portfolios. A spreadsheet optimiser was utilised to allocate assets under a variety of scenarios.

Introduction

Over the last 3 years there has been a rapid increase in house prices in a number of countries, including New Zealand. This has resulted in significant number of investors attempting to optimise their wealth by purchasing one or more residential rental properties. Investors have been encouraged to expand their housing interests by “get rich” seminar presentations, books and software from organisations such as Richmastery (2005). The liberal lending policies adopted by Banks competing for market share, combined with low mortgage interest rates, acted to fuel the housing market. Investors are typically able to fund the purchase of rental housing by borrowing against the increased equity in their family homes. Servicing the additional borrowing is done from the rental income stream, if this is insufficient then Withers (2004) shows how losses on rental housing can be offset against other income. The overall objective is to maximise the amount of capital gain and the best way to do this is by owning multiple properties.

Traditionally investor housing has not been seen as a particularly attractive investment option. Jones (2005) argues investors will achieve better returns in the commercial property sector and Newland (2004) predicts the current housing bubble is about to burst. Also, New Zealand has a history of government intervention in the rental housing market through rent controls, subsidised state housing and private sector rental subsidies. More recently the slow decline in the rate of home ownership in New Zealand, mainly due to affordability considerations, has underpinned both rents and house prices in the lower priced housing market. As a consequence first home buyers have been subjected to increasing competition from investor purchasers. So, what sort of returns being achieved from investor housing? To answer this question involves the construction of a total returns index for investor housing. Such an index makes it possible to compare the investment performance of housing both between cities and with other asset classes. Most of the information needed to construct a total returns index is currently available. Quotable Value NZ (QVNZ) (2004) has a long running series tracking movements in house prices by comparing average sale prices to average rating valuations and chaining these over time. The Department of Building and Housing (DBH) (2005) holds all private sector tenancy bonds and regularly publishes reliable information on residential rents.

However, two elements essential for the construction of an index have been lacking. Firstly, research establishing the relationship between gross income and net income. Secondly, research determining the linkage between rental house prices and overall median house prices.

The first section of this paper reviews some of the relevant literature on property indices. The next section summarises a survey of private sector landlords conducted by the authors aimed at providing the missing information on net incomes and rental house prices. The third section of the paper combines the findings from the survey with the sales and rental data bases to produce a total returns series over the period 1994-2004. The final section of the paper briefly discusses how portfolio theory could be applied to the allocation of rental housing between several cities.

Property Indices

The total annual returns (before tax and debt servicing) from property investments comprise the cash flows from income (rent less vacancies) less the annual operating expenses (rates, repairs and maintenance, insurance, management etc), plus changes in the value of the property less capital expenditure. This is the approach used by the Property Council of New Zealand (2004).

Thus

$$TR\% = \left(\left(\frac{GI - EXP}{CMV} \right) \times 100 \right) + \left(\left(\frac{(CMV - PMV) - CE}{CMV} \right) \times 100 \right)$$

when

TR%	=	Total return for the period (before tax and debt servicing) as a percent of the current market value of the property
GI	=	Gross income (potential rent less vacancies and bad debts)
EXP	=	Annual expenses associated with operating the property (rates, insurance, management, repairs and maintenance and other expenses such as accounting)
CMV	=	Current market value of the property
PMV	=	Previous market value in last period
CE	=	Capital Expenditure in current period

A property index can be constructed by aggregating the returns from individual properties using the above methodology and then chaining the total returns per period over time. For example if the index number for the base year is set at 100 and the total return in the first year is 10 percent (say 5 percent net yield plus 5 percent increase in house prices) then the index number at the beginning of the second year will be 110. Having a common index number in the base year enables index users to compare property returns between different localities, classes of property and other asset classes.

Normally the most difficult component to estimate with property indices is the changes in the market value of houses from one period to the next. Since the majority of housing in western countries is owner-occupied most housing indices are price indices and just estimate changes in house prices rather than total returns. The extensive housing index literature identifies four main transaction based approaches, the median price method, the hedonic method, the repeat sales method and the hybrid method.

Median Price Method

The median price method computes percentage price changes in the median house price between periods. This statistic is commonly reported by professional real estate groups in the mass media and has the advantage of being both timely and easy to understand. The median price is more useful statistic than the average price but Rossini et al (2002) point out results can be skewed by a period when most of the sales are at the expensive end of the market because lower priced housing isn't selling. In addition, the median statistic is volatile with small sample sizes and suffers from a constant quality problem because over time new houses are typically larger and more elaborate than older houses.

Hedonic Method

Hedonic indices are described by a variety of authors including Pendelton (1965), Linneman (1986), Case et al (1991), Haurin & Hendershott (1991), Clapp et al (1991) and Malpezzi (1998). These indices utilise property sales information and multiple regression analysis to control for quality differences between houses. Hedonic methodology has been used for more than 30 years in mass appraisals for rating and taxing purposes. When the hedonic method is used to establish house price indices the

variables used to account for changes in value over time become very important. The usual method of measuring time changes is to use dummy variables. These are coded (0, 1) according to the sale date to account for changes in values between time periods. Costello (1997) commented that where large numbers of transactions are available then hedonic methods should produce a robust price series for empirical research.

The main issue with the hedonic method is correctly specifying the regression equations to minimise the amount of unexplained variance. Correct specification relies on the availability of good data and the skill of the analyst.

Repeated Sales Method

The repeated sales index method uses transaction data for properties that have sold more than once. This method was pioneered by Bailey, Muth & Nourse (1963) and is known as the BMN method.

The BMN method avoids the variable specification problems inherent in the hedonic method. The index is compiled by regressing the log price changes between previous and current sales on a set of dummy variables. Case & Schiller (1987) refined the BMN method by using a procedure to down weight the influence of transactions with longer time periods between sales. Clapp & Giaccotto (1999) pointed out several disadvantages with the repeated sales method. These included the selection bias from ignoring single transactions, the issue of “starter homes” and problem properties that may transact frequently, and the need to revise the whole index every time a new set of data is added to the index. The repeated sales method makes the constant quality assumption that over time depreciation will be offset by maintenance expenditure. However, unless the analyst actually inspects the houses it is not possible to validate this assumption and some houses may have been extensively refurbished and upgraded while others may not have been properly maintained. Larsen & Sommervoll (2004) use a large set of repeated sales to segment Norwegian data and show how different types of apartments in Oslo have appreciated at different rates.

Hybrid Method

In an attempt to overcome some of the difficulties with the hedonic and repeated sales method Case & Quigley (1991) introduced a hybrid method which combined aspects of repeated sales and hedonic methodology. This method had the advantage of using all transaction data and appeared to increase the efficiency of the index estimate. A criticism of this approach was the complexity of the hybrid method and Quigley (1995) discussed a simplified hybrid model.

Quotable Value Index

In New Zealand the most commonly used property price indices are the QVNZ indices based on comparing sale prices with the periodic rating valuations and chaining these over time. The QVNZ rating valuations make extensive use of regression analysis methodology to set the rating valuations. Although Lum (2004) has some reservations about this type of approach it is transaction based, inexpensive to compile and accepted in the New Zealand residential market. In an unpublished report Singleton (2003) found Palmerston North City house price models based on rating valuations were generally more highly correlated to sale prices than repeated sales models and regression models that did not use the rating valuations. Rating valuations are an important consideration for New Zealand residential property investors when they are formulating their bid/ask prices. More recently Bourassa et al (2005) confirmed that the cost effectiveness and robustness of the methodology used in the QVNZ indexing system. Bourassa found that the QVNZ index was strongly correlated with the hedonic method and recommended that the sales price/assessment methodology be seriously considered by government agencies, given the number of advantages and few disadvantages. Clapp et al (1991) had shown that while rating valuations contain errors in the assessments the size of the bias was negligible.

The QVNZ indices used in the construction of total returns index described later in this paper reduce the constant quality problem because quality changes that require a building consent are reflected in the rating valuation assessments. However, this still leaves the problem of subtle quality improvements not being reflected in the rating valuation, unless the valuers inspect the property during the sales analysis process.

Total Returns Indices For Housing

In the United Kingdom both the Association of Residential Letting Agents (ARLA) (2004) and the International Property Database (IPD) (2004) produce information on the returns from residential investment. ARLA uses data from mail questionnaires completed by letting agents. The IPD residential index has wider coverage than the ARLA index and qualified valuers using the RICS guidelines assess the investment value of a sample of representative properties used in the index. In the US the National Council of Real Estate Investment Fiduciaries (NCREIF) (2005) publish a number of property indices, including one for apartments. The main disadvantage with professional valuations is the valuation smoothing effect as pointed out by a variety of academic writers including Newell and MacFarlane (1998). This means the valuations based indices tend to be less volatile than transaction indices and lag the market.

The Survey

The main objectives of the survey were firstly to establish the relationship between gross and net income and the capitalisation rates for residential investor housing and secondly to determine the relationship between the value of rental housing and the value of housing as a whole.

Survey Methodology

A mail questionnaire was sent directly to the property owners. As more than 80 percent of private sector rental property in New Zealand is self managed the mail questionnaire method was considered to be the most reliable survey method.

A random sample of 3000 private sector landlords from throughout New Zealand was generated from the DBH (Tenancy Services Division) database. This data base is comprehensive and the chances of sample bias are small since under the Residential Tenancies Act all tenancy bonds must be lodged with the DBH.

A total of 907 landlords responded to the survey before the cut off date at the end of June 2004. This represented a 30.2% response rate. A reminder letter was not used due to the complex mailing procedure and additional cost considerations. The 907

landlords represented 1585 separate properties, on average 1.74 properties per landlord.

Survey Results Summarised

The 1585 properties in the survey comprised three main groups; houses (1062), flats (314) and apartments (90). There were a variety of other property types on one title including; owner occupied houses and rental flats and owner occupied houses and rented bed sitters. The houses were predominantly 3 bedrooms, detached and located in the suburbs. This paper only reports on the analysis of the houses group because there is currently no reliable time series data on the prices for apartments and flats. The houses group typically comprises of around 60 percent of the monthly volume of new tenancies recorded by the DBH.

The respondents were asked to provide information on how long they had owned the property, the price paid, the expenses and their estimate of the current market value. In addition, there was a question on their capital expenditure over the previous year. This information was used to calculate capital gains, gross and net yields and to compare the average of the owners' valuations with house sales statistics. According to Keil & Zabel (1999) there may be a tendency for owners to slightly over value owner-occupied housing. In the case of this survey the median time of ownership was so short it was possible to compare the purchase price with the estimated sale price and compare this with changes in the property market over the period. The figures supplied appear to be in line with the existing QVNZ house price index increased 19.8% in 2003 and Real Estate Institute (2004) statistics show the median price of a house increased by 18% in the period May 2003 to May 2004.

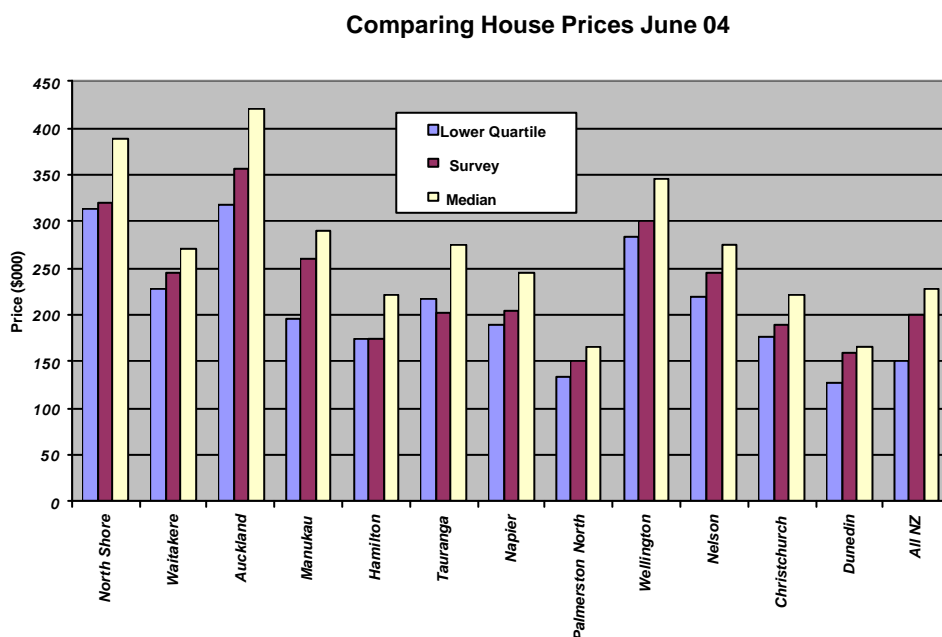

When building a residential rental total returns index a decision has to be made about which set of house price data typifies private sector rental properties. This is important because price has a direct influence on the yields. The most obvious alternatives are the median price or the lower quartile price, both published regularly by QVNZ. Figure 1 compares the median prices reported from the survey with the QVNZ median and lower quartile prices for the main cities and for all New Zealand. This chart shows the survey median lying between the QVNZ figures for most cities,

particularly the larger cities with more robust data sets. On average this figure was within 3 percent of the median prices shown in the survey.

Another way of looking at the where private sector rental housing sits in the overall house price spectrum is to consider the total percentage of rental housing and the proportion of this that is central government and local authority social housing. By 2001 rental housing comprised around 28 percent of the housing stock and was increasing at about 0.6 percent per year so by 2004 rental housing comprised around 30 percent of the national housing stock. Private sector rental housing comprises around 80 percent of the rental housing stock. Owner-occupier rates are lowest in the cities, particularly Auckland City which will have 50 percent rental housing within the next 7-10 years. In general the housing values are lower with social housing due to the stigma associated with some of the state housing neighbourhoods. Private rental housing can usually be switched in and out of the owner occupier market, depending on market conditions.

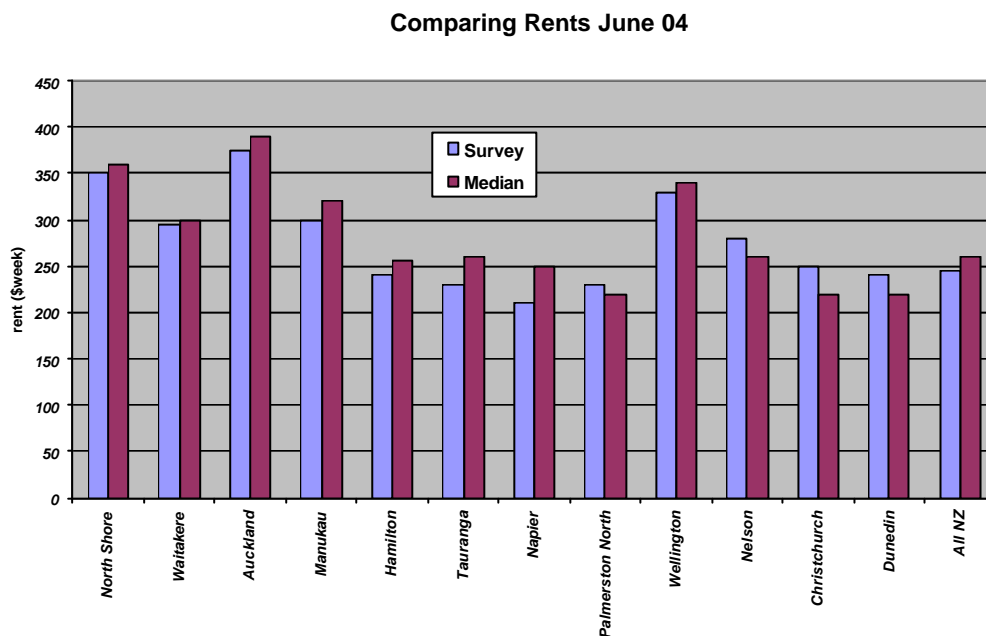

Where the percent of rental properties is high it is not realistic to assume rental houses are confined to the less expensive suburbs. Analysis of data from Statistics New Zealand (2001) from the 1991-2001 censuses shows rental housing increasing across all established suburbs and the same is true across all cities.

Figure 1

An additional test to see if the responses from the questionnaire are reflective of the rental market as a whole is to compare the median rental levels for houses from the DBH (Tenancy Bond Division) data base with the median rents reported in the survey. This comparison is reported in Figure 2 and shows a strong correlation. Nationally the median rent for houses from the survey was \$245 per week and from the DBH data \$260. On average, across all the locations shown in Figure 2, the two sets of data are within 1.7% of each other.

Figure 2

Analysis of the survey data showed vacancies averaged 1.5 weeks per year and expenses averaged 23 percent of gross rentals. Where rental houses are self managed by the landlord a management fee of 7 percent was included to reflect the opportunity cost of the landlords time and provide a basis for comparing investor housing with other asset classes.

Developing the Index

Annual returns to investor housing comprise cash flow from the rents less expenses and changes in the value of the property from one year to the next. The annual cash flow was estimated by taking the DBH median rental information for houses and

adjusting for vacancy (1.5 weeks) and expenses (23 percent of gross income) as analysed from the survey. For example, in the case of North Shore City in 1994 the index figure (rounded to whole number) computed as 116 which is 16 percent up on the 1993 base value for the index of 100. The 16 percent increase comprised a net yield of 6.02 percent (see Table A in Appendix 1) and increases in house prices of 9.9 percent (see Table B in Appendix 1).

The net yields derived from the survey data for June 2004 are closely aligned with the net yields shown in Table A of Appendix 1. It was not possible to verify the older net yield data from the 2004 snapshot so this should be treated with caution since the relationship between gross income and net income may have changed slightly over time. Further survey work will be needed to sustain the index on an ongoing basis and obtain more comprehensive information on regional variations in the ratio of vacancies and expenses to rental income. A lack of reliable rental data prior to 1993 precluded the index being able to show a longer time series. Calculating the net yield also involved making a decision about which set of house prices to use when constructing the index. The results shown in Figure 1 indicate that on average rental house price fall between the QVNZ median and lower quartile house prices. The decision was made to average the median and lower quartile house prices on the basis that this was a more accurate reflection of the growing population of private sector rental houses than simply using the lower quartile house price data. The QVNZ house price indices for each City were used to compute the annual changes in property values.

Given the above assumptions then a total returns series was developed for the period June 1993 to June 2004. Table 1 shows the total returns indices over this period for the main urban centres and for all New Zealand. The net yield data was characterised by yields decreasing over time in all localities and yields being highest in slow growing localities and lowest in fast growing areas. Net yields are now below the market rate of interest on bank deposits and government bonds for most localities. This means that investors are increasing reliant on capital gains in the value of housing to offset the increased risks associated with rental housing investments.

The changes in house prices over time are largely related to demographic trends and the resultant demand pressures. Internal migration trends show a drift to warmer

climates and jobs. This has meant significant growth in the Auckland region and slow growth in the South Island and on the western side of the North Island. Immigrants are mainly from China and prefer to live in Auckland.

The total returns indices are based on un-leveraged returns before tax. As the interest rate on borrowed money has generally been well under the total returns reflected in Table 1 many investors will be exceeding these returns. It is important to consider un-leveraged returns as a starting point when making comparison with the total returns from other asset classes because the degree of leverage is something personal to the risk/return profile of individual investors.

Table 1: Total Returns Indices

	1993	1994	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004

Table 2 shows the percent average returns over the eleven year period June 1994 to June 2004 as well as the percent standard deviations and the risk ratios (average return divided by the standard deviation) associated with these returns. Generally the results in Table 2 confirm lower average returns are associated with lower risk areas but Wellington City is a notable exception since it shows high returns and low risk. The lower risks associated with Wellington City are thought to relate to its position as the capital city and the increasing percentage of stable public service renters. Past returns give some guidance to likely future returns as they include the long term demographic trends of internal migration being characterised by a population drift both North and

East and external immigration focusing on the Auckland region. The cyclical fluctuations in national net migration figures are thought to account for part of the volatility of total returns, particularly in the Auckland region.

Table 2: Volatility of Returns

	<i>Average</i>	<i>Standard Deviation</i>	<i>Risk ratio</i>
<i>North Shore</i>	13.2	8.3	0.6
<i>Waitakere</i>	13.9	10.1	0.7
<i>Auckland</i>	14.3	9.0	0.6
<i>Manukau</i>	12.9	7.7	0.6
<i>Papakura</i>	11.8	10.4	0.8
<i>Hamilton</i>	10.4	7.2	0.6
<i>Tauranga</i>	13.0	8.6	0.6
<i>Napier</i>	12.7	8.0	0.6
<i>Palmerston Nth</i>	9.8	4.5	0.4
<i>Porirua</i>	13.3	5.1	0.3
<i>Upper Hutt</i>	12.1	4.4	0.3
<i>Lower Hutt</i>	13.1	4.3	0.3
<i>Wellington</i>	14.5	4.7	0.3
<i>Nelson</i>	12.4	9.6	0.7
<i>Christchurch</i>	11.2	8.2	0.7
<i>Dunedin</i>	11.5	8.9	0.7
<i>Invercargill</i>	11.9	11.0	0.9
<i>All NZ</i>	12.9	6.5	0.5

Index Sensitivity

The gross rental and house price information used in the construction of the total returns index has been taken from reliable government agency data bases. The survey of residential property investors provided a 2004 snapshot of the relationship between gross rents and net income (before tax and debt servicing) as well as the most likely price band to use for investor housing

Back casting the index to 1993 is based on the assumption that the ratio of expenses to gross rents has been consistent over time. This is taken as the most likely scenario. To test the sensitivity of the key assumptions the indices were recalculated under both more optimistic and more pessimistic scenarios. The more optimistic scenario assumed the same ratio of expenses to income and vacancy rate as the most likely scenario and based the house prices on lower quartile data. The pessimistic scenario

used the same set of house prices as the most likely scenario but increased expenses from 23 percent to 26 percent of gross rents and increased the annual vacancy rate from 1.5 weeks to 3 weeks.

The results of this analysis are summarised in Table 3 showing the average of the three scenarios over the period June 1994- June 2004. The difference column is the optimistic average return less the pessimistic average return. It is interesting to note that there are relatively small differences in the average total returns (about 1.2 percent) between the pessimistic and optimistic scenarios. This illustrates just how much total returns are being driven by changes in house prices and the relatively small influence that running expenses have on total returns.

Table 3: Index Sensitivity

	<i>Pessimistic</i>	<i>Most likely</i>	<i>Optimistic</i>	<i>Difference</i>
<i>North Shore</i>	12.8	13.2	13.8	0.9
<i>Waitakere</i>	13.5	13.9	14.5	0.9
<i>Auckland</i>	13.9	14.3	15.1	1.2
<i>Manukau</i>	12.5	12.9	14.0	1.5
<i>Papakura</i>	11.4	11.8	12.5	1.0
<i>Hamilton</i>	10.1	10.4	11.0	0.8
<i>Tauranga</i>	12.6	13.0	13.5	0.8
<i>Napier</i>	12.3	12.7	13.2	0.9
<i>Palmerston Nth</i>	9.3	9.8	10.5	1.1
<i>Porirua</i>	12.9	13.3	14.6	1.7
<i>Upper Hutt</i>	11.6	12.1	12.7	1.1
<i>Lower Hutt</i>	12.7	13.1	14.5	1.8
<i>Wellington</i>	14.1	14.5	15.2	1.1
<i>Nelson</i>	12.0	12.4	12.9	0.9
<i>Christchurch</i>	10.8	11.2	11.9	1.0
<i>Dunedin</i>	11.0	11.5	12.5	1.5
<i>Invercargill</i>	11.3	11.9	13.5	2.2
<i>All NZ</i>	12.5	12.9	14.2	1.6

Portfolio Analysis

Markowitz (1959) introduced the formal concept of using portfolio diversification to reduce risk. His ideas were quickly embraced by the finance discipline and he was later rewarded with a Nobel Prize in Economics. Jaffe and Sirmans (1995) noted that the property discipline was much slower to utilise portfolio theory due to initial scepticism about real world property applications due to the significant data problems relating to the measurement of market return. Transaction costs are also much higher

in property as compared to the stock market and this factor discourages property investors from frequently altering their portfolios. In addition, many residential property investors invest locally because they like to be able to drive by and self manage their rental houses. The total returns index developed in this paper is a first step in providing New Zealand data that can be used for assessing the place of residential property in a mixed asset portfolio.

Ling and Archer (2005) point out investment opportunities should be evaluated on the basis of their influence on the risk/return profile of the whole portfolio. In a property context diversification can be across property types, locations or a mixture of both. In the case of residential rental property investors there may be advantages in diversifying across two or more cities. The total returns indices shown in Table 2 highlight the fact that in some years there are significant differences in returns between cities even though long term average returns may be similar. Investors can exploit these differences by looking for cities with low or negative correlations so as to minimise risk. Table 4 shows the correlation of total returns between cities over the 1994-2004 period. It is noticeable that cities in the Auckland region tend to have negative correlations with those in the Wellington area. This is mostly related to the regions being at different stages on the property cycle rather than fundamental differences in the yields.

Table 4: Correlation Matrix

	<i>N Shore</i>	<i>Waitakere</i>	<i>Auckland</i>	<i>Manukau</i>	<i>Papakura</i>	<i>Hamilton</i>	<i>Tauranga</i>	<i>Napier</i>	<i>Palmerston North</i>	<i>Porirua</i>	<i>Upper Hutt</i>	<i>Lower Hutt</i>	<i>Wellington</i>	<i>Nelson</i>	<i>Christchurch</i>	<i>Dunedin</i>	<i>Invercargill</i>

** Significant at 1% level

* Significant at 5% level

Auckland and Lower Hutt cities have a negative correlation of (-0.32). Construction of a property portfolio where the investment was 50 per cent Auckland and 50 percent Lower Hutt reduces the risk as shown Figure 3. The 50/50 portfolio has a standard deviation of returns of 4.14 percent being less than half Auckland (9.01 percent) and below Lower Hutt (4.38 percent). Diversification results in only a slight trade off in total returns from the riskier Auckland only portfolio. The 50/50 portfolio shows an average return of 13.74 percent. Although locational diversification may not be attractive for the smaller investors who prefer to self manage it is a viable alternative for larger investors and those prepared to employ property managers. The transaction costs of switching property assets around has not been factored into the 50/50 portfolio and as a result the returns for this option may be overestimated slightly.

Figure 3:

Diversification becomes more complicated as additional assets are added to the portfolio. Although the calculations to minimize risk and achieve a target rate of return can be done by hand this is very time consuming. Brown and Matysiak (2000) advise the use of a spreadsheet optimizer such as the Solver add in available in Microsoft Excel and described in the manual by Chester and Alden (1997).

For reasons of geographic diversification and trading yields against capital appreciation an investor may decide to construct a residential portfolio in Auckland, Wellington and Christchurch. Assuming the investor specifies that there should be a minimum of 15 percent and a maximum of 60 percent of the portfolio in each city. The objective is to achieve an asset allocation to minimise the risk. The results of the analysis are shown in Table 5. The optimiser solution is clearly constrained by the minimum and maximum asset allocations for each city. Without this constraint the investor would just buy Wellington houses. If the investor was prepared to take on more risk then Auckland houses would form a larger part of the portfolio at the expense of Christchurch.

Table 5: Weighting the Portfolio

	<i>Return</i>	<i>Risk</i>	<i>Portfolio Weight</i>	<i>Weighted Return</i>	<i>Weighted Risk</i>
<i>Auckland</i>	14.3	9.0	15.0	2.2	1.3
<i>Wellington</i>	14.5	4.7	60.0	8.7	2.9
<i>Christchurch</i>	11.2	8.2	25.0	2.8	2.0
<i>Total</i>			100.0	13.7	6.2

Summary and Conclusions

The snapshot of the private sector residential market compiled from the survey provided the authors with baseline information that enable them to combine the DBH rental and QVNZ house price data bases. Results from the survey showed on average private sector rental housing values sit midway between lower quartile and median house prices. Analysis of the survey also established that median net income is around 77 per cent of gross income. It is acknowledged that there may well be some regional variations and variations over time in the relationship between gross and net incomes, not captured in the indices. Further research with a longer time series will be needed to clarify these issues. However, when tested the indices were shown to be relatively insensitive to changes in vacancy and expenses. The reason for this is because appreciation in house prices has dominated total returns.

The total returns index developed in this paper is a transaction based index utilising actual rents and property sales data. This index does not rely on periodic property valuations and suffer from valuation smoothing effects. The index attempts to overcome the constant quality problem by utilising QVNZ house price indices, which include all house sales. Further research is needed to determine if changes in the value of rental housing occurs at a similar rate to the total population of houses and the extent the QVNZ index captures the level of capital expenditure on housing.

Net rental yields have continued to trend down over the last decade as increases in house prices have not been offset by similar increases in rents. Currently net rental yields are below the market rate of interest and total returns are increasingly reliant on capital appreciation.

In comparison with other asset classes, over the last decade, investors in rental housing generally achieved good, but not spectacular, returns. Residential rental property is typically self managed and this does allow investors to increase their cash flows by substituting their own labour for outside management. Self management

also gives investors the chance to further control the expenditure items such as repairs and maintenance by utilising their own labour to minimise the use of outside contractors.

There are significant differences in the total returns being achieved between cities and the higher yields in the slower growing cities are not enough to offset the higher total returns in the faster growing areas. The total returns in Auckland and Wellington cities are roughly the same but Wellington has an appreciable lower standard deviation of returns.

There is an opportunity for residential investors to reduce their exposure to risk by diversifying their rental housing portfolios and exploiting the negative correlations between cities. Optimising the geographic allocation of rental houses within a portfolio according to specified risk/return criteria can be accomplished by using the Solver application in Excel. The main limitation with applying portfolio theory to investor housing is that the past performance of the property market may not be a good indicator of future performance. This means investors need to be aware of underlying demographic trends and the effect of these on future capital growth prospects.
